

<sup>1</sup> The impact of diabetes on labour market outcomes in  
<sup>2</sup> Mexico: a panel data and biomarker analysis

<sup>3</sup>

## Abstract

Recent evidence for Mexico suggests important differences in health status between people with diagnosed and undiagnosed diabetes. However, there is at best scarce evidence on the economic consequences of diabetes, especially in contexts where the condition often remains undiagnosed, as is typically the case in low- and middle income countries. Using Mexican longitudinal as well as biomarker data we estimated the impact of diabetes and diabetes duration on employment probabilities, wages and working hours. We further explored how these effects differed for those with diagnosed and undiagnosed diabetes. For the longitudinal analyses nationally representative data from 11836 men and 13745 women 15 to 64 years old were taken from three waves (2002, 2005, 2009) of the Mexican Family Life Survey. We estimated a fixed effects model to account for unmeasured time-invariant confounders of diabetes. We found a reduction in the probability of being employed of 5.4 and 5.9 percentage points for men and women, respectively, but no effects on hours worked or wages. Employment probabilities fell gradually with each year since diagnosis. Using cross-sectional biomarker data, we observed that 68% of those exhibiting glycated hemoglobin (HbA1c) levels above the clinical diabetes threshold did not self-report a diagnosis, hence were undiagnosed. Nevertheless, regression analysis revealed that there was no association of diabetes with labour outcomes for undiagnosed women or men. This suggests that results based on self-reported diabetes cannot be extended to the considerable population with undiagnosed diabetes, likely because of a selection of people in worse health and with a longer diabetes duration into the diagnosed population. An earlier diagnosis and improved treatment of diabetes therefore may prevent adverse health effects and related economic hardship in Mexico.

## 1. Introduction

Diabetes, a disease characterized by elevated blood glucose levels due to the body's inability to use insulin properly, has in the last two decades increasingly become a global

31 problem, with over two-thirds of people with diabetes living in low- and middle-income  
32 countries (LMICs) (International Diabetes Federation 2015). In Mexico, diabetes preva-  
33 lence has grown from 6.7% in 1994 to 14.4% in 2006 (Barquera, Campos-Nonato, et al.  
34 2013) and 15.8% in 2015. Diabetes has become the number one contributor to mortal-  
35 ity (International Diabetes Federation 2015), by increasing the risk for heart disease and  
36 stroke, blindness, kidney disease and neurologic problems, foot ulcers and amputations  
37 (Reynoso-Noverón et al. 2011). However, via effective self-management of the disease  
38 through regular monitoring, behaviour change and medication adherence, the occurrence  
39 of complications could be avoided or delayed in many cases (Gregg et al. 2012; Lim et al.  
40 2011).

41 The observed increase in diabetes incidence has been attributed to a deterioration in  
42 diet and a reduction in physical activity (Barquera, Hernandez-Barrera, et al. 2008; Basu  
43 et al. 2013), while genetic predisposition among Mexicans with pre-Hispanic ancestry may  
44 also play a role (Williams et al. 2013). The onset of diabetes has been occurring at an  
45 ever earlier age in Mexico (Bello-Chavolla et al. 2017), increasing the risk of complications  
46 occurring during the productive lifespan. Only a minority of patients in Mexico achieves  
47 adequate blood glucose control (Barquera, Campos-Nonato, et al. 2013). Moreover, dia-  
48 betes is related to diseases, including depression, hypertension and cardiovascular disease  
49 that impose a heavy burden onto the health system (World Health Organization 2016).

50 Despite the catastrophic impact of diabetes on health, its economic consequences, in  
51 particular in LMICs, have received little attention. This applies in particular to the evi-  
52 dence on the effects of diabetes on labour outcomes (Seuring, Archangelidi, et al. 2015).  
53 In high-income countries substantial economic losses have been observed (Brown, Pagán,  
54 et al. 2005; Brown, Perez, et al. 2011; Brown 2014; Latif 2009; Minor 2011, 2013; Mi-  
55 nor and MacEwan 2016). A rare LMIC study exploited a natural experiment in China  
56 and found a significant reduction in income due to a recent diabetes diagnosis (Liu and  
57 Zhu 2014). A study for Mexico, using cross-sectional data from 2005, found a significant

( $p < 0.01$ ) reduction in employment probabilities for males by 10 percentage points (p.p.) and for females by 4.5 p.p. ( $p < 0.1$ ) (Seuring, Goryakin, et al. 2015). Most existing studies relied on instrumental variable (IV) estimation, using the genetic component of diabetes based on its family history, to address the potential endogeneity of diabetes. However, family history of diabetes may also proxy for other genetically transferred traits, including unobserved abilities, as well as intrahousehold or intergenerational dynamics that impact labour outcomes directly; the validity of this IV therefore remains debatable. Panel data methods provide the opportunity to account for time-invariant unobserved individual characteristics, which may play an important role, but—to the best of our knowledge—have not yet been used. Such unobservables, for instance hunger or nutrient deficiency experienced in early life, could adversely affect health as well as the propensity to develop type 2 diabetes later in life (Ewijk 2011; Li et al. 2010; Sotomayor 2013). Additionally, there may also be long-term effects on labour outcomes—either directly through reductions in contemporaneous productivity (Currie and Vogl 2013), or indirectly by limiting educational attainment and human capital accumulation (Ayyagari et al. 2011). These unobservables thereby present a major source of a potential bias that can be accounted for by panel data estimation.

In parallel to these identification challenges, heterogeneity in impact and measurement across the population also deserves further investigation. Recent evidence from Mexico points to a strong positive relationship of diabetes duration with mortality due to diabetes related complications (Herrington et al. 2018). A longer disease duration was found to be related with higher glycated hemoglobin (HbA1c) levels, and undiagnosed diabetes had the lowest diabetes related mortality risks. The latter points to potential selection issues when using self-reported diabetes data to investigate economic outcomes. Those who self-report, and hence tend to be diagnosed, are in worse health than those undiagnosed. This can lead to an overestimation of the economic effects of diabetes, in particular in populations with a large undiagnosed population, such as in many LMICs (Beagley et al.

2014). So far, however, little evidence exists on the economic impact according to diabetes severity, duration or for those with undiagnosed diabetes.

The objective of this study was to provide new evidence on the impact of diabetes on labour outcomes, adding to previous work by paying close attention to the challenges of unobserved heterogeneity, to the chronic nature of diabetes and to undiagnosed diabetes. We used three waves of the Mexican Family Life Survey (MxFLS), covering the period 2002–2012. Applying a fixed effects model we accounted for time-invariant heterogeneity when assessing the impact of self-reported diabetes and time since diagnosis on labour outcomes. To assess the role of undiagnosed diabetes we used biomarker data from the last wave of the MxFLS.

## 2. Data

This paper used data from the Mexican Family Life Survey (MxFLS), a nationally representative longitudinal household survey, containing three waves conducted in 2002, 2005–2006 and 2009–2012. The baseline sample collected information from 35,000 individuals from 8,400 households in 150 communities throughout Mexico. It is the only longitudinal household survey in Mexico that provides data on a wide range of social, demographic, economic and health characteristics (Rubalcava and Teruel 2013). Because the survey followed participants moving within Mexico as well as to the US, around 90% of the original sample have been reinterviewed in the third wave. Our samples were restricted to the working age population (15–64) and excluded pregnant women. Pregnant women have an increased diabetes risk and may not be able to work. Since their inclusion may have biased the estimates, we dropped all observations of women reporting to be pregnant at the time of the survey (N=764). We also dropped those reporting to be in school. The first part of the analysis used all three waves, exploiting the panel structure of the data. The second part used a biomarker subsample of the third wave (2009–2012). Because the biomarker

sample included everybody above the age of 44, but only a random subsample of those aged 44 or below (Crimmins et al. 2015), its age structure was older and hence its self-reported diabetes prevalence higher. The analysis therefore compares with self-reported data for this specific subsample only.

Our outcome variables of interest were employment status, weekly working hours, hourly wage, and occupation. Employment status was defined as having carried out an activity that helped with the household expenses the last week while working for at least four hours per week. We explicitly included informal employment and employment without monetary remuneration, for instance in family businesses. Hourly wage was constructed as reported monthly income from the first and second job, divided by average number of weeks per month and weekly working hours. Labour income was obtained from the response to questions on wages, income from piecework, tips, income from extra hours, meals, housing, transport, medical benefits and other earnings, or from the response to a question on aggregate labour income for the entire month. We adjusted calculated wages for inflation in the year of interview and considered the log of real wages. Due to a considerable number of missing or zero income reports, the sample used for the wage estimation was smaller than the sample for working hours. Working hours were combined from both the first and a potential second job.

Descriptive statistics for the entire panel sample show that over 80% of men with diabetes and 87% of men without diabetes reported some form of employment, compared to 26% of women with diabetes and 37% of women without diabetes (see Table 1). Interestingly, men did not report considerably higher hourly wages than women but worked more hours per week. There were also little differences in working hours and wages between men and women with and without diabetes. Men worked more often in agricultural jobs while women were more likely to be self-employed or in non-agricultural wage employment. The educational attainment of women was lower than that for men on average. Similarly, those without diabetes were better educated than those with diabetes. Further, the diabetes

sample is about 15 years older on average than the non-diabetes sample, both for men and women.

Notes Mean values. Diabetes refers to self-reported diabetes.

The first part of the analysis focused on the relationship of labour outcomes with self-reported diabetes, which was based on the survey question: “Have you ever been diagnosed with diabetes?”. Because the data did not distinguish between type 1 and type 2 diabetes, we assumed that the estimates represented the impact of type 2 diabetes, by far the most common type of diabetes in Mexico. As a robustness check, we re-estimated our main results categorizing diabetes into early-onset and late-onset cases, according to the age at which diabetes was first reported in the survey. This was a similar approach to Alegre-Díaz et al. (2016), who assumed that everybody diagnosed before age 35 and using insulin had type 1 diabetes. Accordingly, we assumed that those first reporting a diabetes diagnosis before the cut-off had type 1 diabetes while those above had type 2 diabetes. Nonetheless,

149 because we cannot warranty that this is 100% accurate (as it may be unlikely that both  
150 populations consisted exclusively of one type of diabetes) we preferred to think of the  
151 groups as of early- and late-onset groups. This separation also provides information about  
152 the effects for different age groups, as the late-onset group had an average age of onset of  
153 50 compared to 28 for the early-onset group. In the pooled data, which combines all three  
154 waves, diabetes was self-reported by 5% of men and 6% of women. This is consistent with  
155 other reports from Mexico for the time, showing a prevalence of diagnosed diabetes of 7.5%  
156 in 2006 in a sample also including people over the age of 64 (Barquera, Campos-Nonato,  
157 et al. 2013). Apart from self-reported diabetes, which was available in all rounds, we also  
158 used information on the self-reported year of diagnosis as well as biometrically measured  
159 HbA1c levels for a subsample of respondents from the third wave.

160 Information on the self-reported year of diagnosis, reported in the third wave, allowed  
161 us to construct a measure of time since diagnosis. For those also present in previous waves,  
162 we inferred the time since diagnosis by the difference between the year of the interview  
163 and the year of diagnosis. This allowed us to use panel data methods for the duration  
164 analysis as well, however limited to those reporting the year of diagnosis in the third wave.

165 The second part of the analysis assessed the role of undiagnosed diabetes. The biomet-  
166 rically measured blood glucose value that allowed us to identify those with undiagnosed  
167 diabetes, was available for over 6000 respondents in the third wave. We used the inter-  
168 nationally recognized cut-off of an  $\text{HbA1c} \geq 6.5\%$  to define diabetes as recommended by  
169 the World Health Organization (WHO) (World Health Organization 2011). As we show  
170 in Supplementary Table S6, 19% of self-reported diabetes cases had HbA1c levels below  
171 the diabetes threshold. We dropped those for our analysis as it was not clear if they  
172 had misreported their diabetes status or had achieved these low levels as a result of their  
173 successful disease management. Analysis including those cases led to qualitatively similar  
174 results (results available on request).

### 3. Estimation strategy

To investigate the relationship between self-reported diabetes and three labour outcomes—employment, weekly working hours and wages—we estimated a fixed effects model. The fixed effects model accounts for the potential bias introduced by time-invariant unobservables, providing an estimate of the effect for cases that received a diagnosis throughout the survey.

$$Y_{it} = \beta_0 + \beta_1(D_{it} - \bar{D}_i) + \beta_2(X_{it} - \bar{X}_i) + \beta_3\bar{D}_i + \beta_4\bar{X}_i + (u_i + e_{it}), \quad (1)$$

The fixed effects model uses only the within-person variation for identification, i.e. the difference between the diabetes indicator  $D_{it}$  and its cluster mean  $\bar{D}_i$ , so that  $\beta_1$  represented the within-person variation of diabetes over time. The same applies to the other time-varying covariates  $X_{it}$ .  $Y_{it}$  was a binary variable taking a value of 1 if respondent  $i$  reported being in employment at time  $t$  and 0 otherwise. For ease of interpretation we chose to estimate a linear probability model for the effects of diabetes on employment.

To estimate the effect on working hours and wages, our empirical models were estimated conditional on being in employment.  $Y_{it}$  represented the log hourly wage or the weekly working hours over the last year, for respondent  $i$  at time  $t$ .

We also included time variant confounders—as the fixed effects model accounts for time invariant confounding only. We controlled for changes in the level of urbanization, the level of education, the state of residence, marital status, the number of children below the age of six in the household, a quadratic age term and calendar year dummies. We also control for household wealth approximated by a household asset index. We composed an indicator using principal component of household assets and housing following Filmer et al. (2001) (Filmer and Pritchett 2001). The asset index reflected owning a vehicle, a second house, a washing machine, dryer, stove, refrigerator or furniture, any electric appliances, any domestic appliances, a bicycle, farm animals, and accounted for the physical condition

199 of the house, proxied by the type of floor material and water access. In our main regression  
200 models we did not account for body mass index (BMI). While part of the effect of diabetes  
201 may be due to potential adverse effects of obesity, including BMI as a control variable in  
202 the model would have led to attenuated estimates if the diagnosis of diabetes also had an  
203 effect on BMI, which has been shown to be the case in other studies (De Fine Olivarius  
204 et al. 2015; Seuring, Suhrcke, et al. 2018; Slade 2012). Similarly, we did not control  
205 for any diseases that were likely consequences of diabetes, such as heart disease or other  
206 micro- and macro-vascular complications (World Health Organization 2016), as this would  
207 prevent any causal interpretation of the relationship of diabetes with our labour market  
208 outcomes (Angrist and Pischke 2009). Nonetheless, we carried out a robustness analysis  
209 controlling for obesity. Stata 15 was used for all analyses (StataCorp 2017).

### 210 3.1. Labour outcomes and time since diagnosis

211 The chronic nature and irreversibility of diabetes provide good reason to explore the  
212 long term effects post diagnosis. To do this we replaced the binary diabetes indicator of  
213 Eq 1 with a continuous variable indicating years since the diagnosis was first reported.  
214 Simultaneous inclusion of year dummies and time since diagnosis (which varies by one unit  
215 in each time period) would typically not allow separate identification of the coefficient of  
216 time since diagnosis. In this case, identification relied on the presence of people without  
217 diabetes in the sample, for which diabetes duration did not increase.

218 We also considered a spline function that allowed for non-linear effects over time, with  
219  $g(Dyears_{it}) = \sum_{n=1}^N \delta_n \cdot \max\{Dyears_{it} - \eta_{n-1}\} I_{in}$  and  $I_{in} = 1[\eta_{n-1} \leq Dyears_{it} < \eta_n]$ ,  
220 with  $\eta_n$  being the place of the  $n$ -th node for  $n = 1, 2, \dots, N$ . The coefficient  $\delta_n$  captured  
221 the effect of diabetes for the  $n$ -th interval. The effects are linear if  $\delta_1 = \delta_2 = \dots = \delta_n$ .

222 Based on visual inspection (Fig. 1 on page 15) we chose three nodes located at 3, 7 and  
223 12 years after diagnosis. The first three years should capture any immediate effects of the  
224 diagnosis, the years four to seven any effects during time of adaptation to the disease and

the later terms the long term effects. We also estimated a non-linear model using dummy variables for duration groups rather than splines, applying the same duration cut-offs. Because the year of diagnosis was only reported in the third wave, time since diagnosis was not available for those who were not interviewed in the third round. A reported diagnosis in the year of the interview was counted as 'one year since diagnosis'.

### 3.2. Labour outcomes and biometrically measured diabetes

The biomarker analysis consisted of three steps. We first re-estimated Eq 2 to assess the relationship between self-reported diabetes with labour outcomes, but this time for the cross-sectional biomarker sample only, using the following specification:

$$Y_i = \beta_0 + \beta_1 Dsr_i + \beta_2 X_i + c_i + v_i \quad (2)$$

where  $v_i$  were community fixed effects, which reflected local unobserved characteristics, such as access to healthcare, poverty and unemployment in the community. Communities (or *localidades* in Spanish) are the smallest administrative units (nested within municipalities) recognized by the Mexican Institute for Statistics and Geography (INEGI). We did not use household fixed effects since the average number of observations per household was close to one.

In a second step we estimated the relations between biomarker diabetes and labour outcomes, using the following equation:

$$Y_i = \beta_0 + \beta_1 Dbio^d + \beta_2 X_i + v_i + u_i, \quad (3)$$

where  $Dbio^d$  was equal to 1 if HbA1c  $\geq 6.5\%$ .

To estimate the effect of undiagnosed diabetes, we added self-reported diabetes back into the equation (Eq 4).

$$Y_i = \beta_0 + \beta_1 Dsr_i + \beta_2 Dbio_i + v_i + u_i. \quad (4)$$

This changed the interpretation of  $Dbio_i$ , which now reflected the effect on those with undiagnosed diabetes, i.e. the respondents not self-reporting diabetes but with HbA1c levels equal to or above the threshold.

We further investigated the effect of the severity of diabetes on labour outcomes, replacing  $Dbio$  with  $Dbio^c$ , a variable that was 0 for  $HbA1c < 6.5\%$  and increased by one for every percentage point increase in HbA1c for those with an  $HbA1c \geq 6.5\%$  (Eq 5). This allowed us to investigate the effect of a one percentage point increase in HbA1c levels for people with undiagnosed diabetes ( $\beta_2$ ) as well as for those with self-reported diabetes ( $\beta_3$ ).

$$Y_i = \beta_0 + \beta_1 Dsr_i + \beta_2 Dbio_i^c + \beta_3 Dsr_i * HbA1c_i + \beta_4 X_i + v_i + u_i. \quad (5)$$

## 4. Results

### 4.1. Labour outcomes and self-reported diabetes

The results of estimating Eq 1 in Table 2 indicated statistically significant reductions in the probability of employment for men and women with self-reported diabetes. Employment probabilities were reduced by 5.4 p.p. for men and 5.9 p.p. for women. There was no significant relationship between diabetes and working hours or wages.

Dividing the diabetes population into early and late onset groups, men, and potentially also women, saw their employment probabilities negatively affected by a diabetes onset later in life (Supplementary Table S2). In particular, women with an early diabetes onset experienced an adverse effect. For working hours, effects were less precise but may indicated increased working hours for men with an early diabetes onset, while women reduced

their work hours. Finally, we found higher wages for women with an early diabetes onset,  
but no effects for men.

Table 2. **Labour outcomes and self-reported diabetes**

	Employment		Weekly working hours		Log hourly wages	
	Males	Females	Males	Females	Males	Females
Diabetes	−0.054** (0.025)	−0.059** (0.024)	−0.506 (1.499)	−1.998 (2.511)	0.055 (0.068)	0.081 (0.158)

*Notes* Robust standard errors in parentheses. All models include variables for states, urbanization, level of education, marital status, number of children < 6, wealth, health insurance status, age squared and one dummy variable for each calendar year. \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

To assess whether diabetes affected the selection into different types of work, we investigated the role of diabetes for the probability of being in non-agricultural wage employment, agricultural employment or self-employment. We found a reduction in the probability to work in agriculture for women, but not for men (Table 3). Disaggregating the diabetes groups further according to their age showed that most statistically significant relationships were driven by the older-onset group (Supplementary Table S3). For male self-employment, diabetes increased the probabilities to be self-employed in the younger group, while it reduced the probabilities to be self-employed in the older-onset group.

N	20719	20719	20719	26575	26575	26575

*Notes* Robust standard errors in parentheses. All models include variables for states, urbanization, level of education, marital status, number of children < 6, wealth, health insurance status, age squared and one dummy variable for each calendar year. \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

We reestimated all regressions in this section including a binary control for obesity

(BMI  $\geq$  30) (Supplementary Table S7 and Table S8). This led to a reduction in sample size due to the larger number of missing cases for BMI. Obesity itself did not appear to be an independent predictor of any labour market outcome. The estimates of the effect of diabetes remained similar for most outcomes. Only for male employment probabilities, the diabetes coefficient was no longer statistically significant at the 10 percent significance level. Estimating the original model without accounting for obesity, but using the sample with only non-missing BMI cases, showed similar changes in effects (results available on request).

## 4.2. Labour outcomes and time since diagnosis

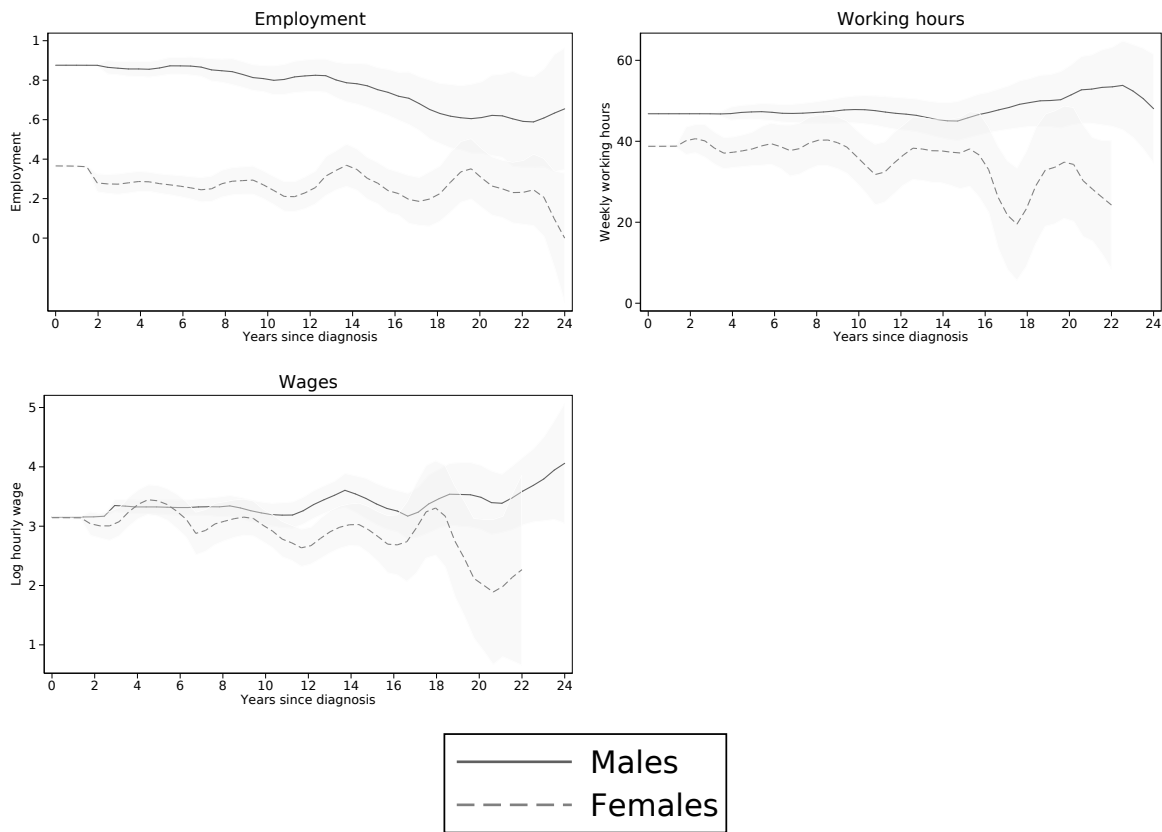

Fig. 1 shows that the probability of employment for men steadily declined as time progressed, using a non-parametric kernel-weighted local polynomial regression. For women, a first drop-off occurred right after diagnosis; though no consistent pattern emerged thereafter. The dynamics for working hours and wages were less clear, with a possibly long term negative trend for women but not for men.

Table 4 panel A shows the results of the linear duration analysis, which indicated that male and female employment probabilities fell every year, with a larger effect shown by the within coefficient.

Wages were reduced for women as diabetes progressed using the linear specification. Using diabetes onset groups, there was no evidence of an effect of diabetes duration for early onset groups (see Supplementary Table S4). Unfortunately the very limited number of diabetes cases in the early-onset group prohibited the estimation of effects of early diabetes onset duration on wages and working hours.

The non-linear results for the spline function and dummy variable approach are presented in panels B and C, respectively. They suggest that the main adverse effects appeared after more than seven years since diagnosis. The same was true for female wages. Reestimating the specifications with a random effects model showed that, at least for the

Figure 1: Employment, wages, working hours and years since self-reported diabetes:  
Kernel-weighted local polynomial regression

*Notes* The shaded areas indicate the 95% confidence intervals.

models with dummies, an immediate reduction in employment probabilities that became stronger the longer a person had diabetes (see Supplementary Table S5). Note that we did not estimate models splitting diabetes in early and late onset groups, as this implied strong reductions in statistical power.

Controlling for obesity, results remained very similar and obesity itself was not found to be affecting any labour market outcome (Supplementary Table S9).

### 4.3. Cross-sectional biomarker analysis

As reported in Supplementary Table S6, 18% of the observations in the biomarker sample were undiagnosed, which accounts for 68% of all cases above the diabetes threshold. Comparing the health status and diabetes risk factors of the diagnosed and undiagnosed diabetes populations suggested that those with self-reported diabetes were older and in worse health, both objectively and subjectively, compared to those undiagnosed.

Table 6 presents the results from estimating Eq. 2 – 5. Panel A confirms the earlier longitudinal results using self-reported diabetes for the cross-sectional biomarker sample. The results in panel B indicate that the relationship with employment became weaker when using diabetes defined by the biomarker instead of self-reported diabetes, in particular for

Table 5. Descriptive comparison of diagnosed and undiagnosed population with diabetes.

*Notes* Results are based on community level fixed effects. Robust standard errors in parentheses. All models include variables for states, urbanization, level of education, marital status, number of children  $< 6$ , wealth, health insurance status, age squared and one dummy variable for each calendar year to account for the multiple years of data collection for the third wave. The wage and working hour models additionally control for type of work (agricultural and self employed with non-agricultural wage employment as the base). \*  $p < 0.10$ , \*\*  $p < 0.05$ , \*\*\*  $p < 0.01$ .

## 5. Discussion

Diabetes is now one of the most common chronic diseases in LMICs, as well as high-income countries (HICs), with potential severe impacts on the health and economic well-being of those affected. Yet rigorous evidence on the economic consequences for LMICs remains scarce.

To address key methodological challenges, this paper used rich longitudinal panel data from Mexico that also contained diabetes biomarkers. The biomarker data showed alarming levels of clinically tested diabetes (27% prevalence) and indicate that a large proportion of the Mexican population (18%) has undiagnosed diabetes.

The paper provided evidence for adverse effects of self-reported diabetes on employment, working hours and wages. While earlier work showed evidence for Mexico for employment (Seuring, Goryakin, et al. 2015), this paper presented, by our knowledge, the

337 first evidence on the relationship of diabetes, working hours and wages. Furthermore, we  
338 added to the study of Seuring, Goryakin, et al. (2015) by using longitudinal instead of  
339 cross-sectional data to identify a causal relationship. We provided first evidence of the long  
340 term impact of diabetes in Mexico and explored the extent and effects of undiagnosed dia-  
341 betes. We confirmed the findings of Seuring, Goryakin, et al. (2015) insofar that we found  
342 an adverse effect of diabetes on male employment. We further showed more conclusive  
343 evidence that also women experience a reduction in their employment probabilities due  
344 to diabetes. Taking into account the differences in employment between men and women,  
345 the found effects translate into relative reductions of their employment probabilities of 6%  
346 for men and 14% for women. We also found that the effects were mainly driven by those  
347 with a diabetes onset at a relatively later state, consisting of older people with most likely  
348 type 2 diabetes. This was also found by Seuring, Goryakin, et al. (2015) in their stratified  
349 analysis of an older and younger age group. Analyses of the long term impact indicated  
350 that the employment probability fell gradually in the years following diagnosis. The results  
351 using a non-linear model were less clear, potentially due to reductions in statistical power,  
352 but suggested that adverse effects became stronger with time since diagnosis. The linear  
353 effect contrasts with estimates for the USA, where such an effect was absent; however  
354 allowing for non-linearity, revealed falling employment probabilities after 11 to 15 years  
355 for females and after 2-5 years for males (Minor 2013).

356 Overall, a relationship of diabetes and working hours or wages was mostly absent.  
357 Although any explanation at this point is speculative, it may be that higher paid and more  
358 educated individuals were able to remain employed without experiencing wage reductions,  
359 for instance due to their particular set of skills. They may also have had access to better  
360 health care leading to better diabetes related health outcomes. Low paid workers, on the  
361 other hand, may have lacked access to quality diabetes care, making it more likely that  
362 they developed severe complications earlier (Flores-Hernández et al. 2015). They may  
363 also have been more likely to be in informal employment and low skilled jobs with less job

security, and thus more prone to being laid off and replaced with healthier workers.

We found that self-reported diabetes cases were not representative of the entire diabetes population in Mexico. A large share of people with diabetes were undiagnosed and significantly healthier and younger, suggesting a selection into the diagnosed group based on the severity and duration of diabetes. Consequently, diabetes as defined by the HbA1c threshold, was less related to reduced employment probabilities compared to self-reported diabetes. Further analysis showed that this was due to the absence of an association between undiagnosed diabetes and employment. These results are similar to those found for the USA, where no statistically significant relationship was observed between undiagnosed diabetes on employment, while a significant effect of diagnosed diabetes was observed (Minor and MacEwan 2016). Our results further indicated that the difference in employment effects of diagnosed and undiagnosed diabetes was not mediated by current HbA1c levels. This is similar to findings for Mexican-Americans in the USA, where employment outcomes were unrelated to higher HbA1c levels (Brown, Perez, et al. 2011). A possible explanation may be that HbA1c levels are primarily informative for the last three months, and are not the only or best indicator for the severity of diabetes. Overall, it seems that a longer diabetes duration with its related health consequences, and selection into the diagnosed population based on emerging diabetes related health problems, could have been driving the adverse economic effects among those with a self-reported diagnosis.

Our study had several limitations. While our model accounted for any time-invariant confounding, the estimates may have been affected by unobserved time-variant confounders. Reverse causality, where employment status affects the propensity to develop or be diagnosed with diabetes, may also have played a role. Existing studies that looked at this particular direction of causality, however, have not found strong evidence for an effect of employment status on diabetes (Bergemann et al. 2011; Schaller and Stevens 2015), though they were carried out in HICs. We did not control for the effects of obesity, hypertension, self-reported health or other diseases in our models due to the high probability

391 that they were affected by diabetes themselves, which would have made a causal interpre-  
392 tation of the estimates more difficult. Robustness checks including obesity indicated that  
393 our main findings remained mostly unchanged and that any occurring changes were likely  
394 the result of a smaller sample size rather than of the inclusion of obesity. For the duration  
395 analysis an additional limitation, imposed by the data, was that the year of diagnosis was  
396 only reported in the third wave. While this still allowed us to construct an estimate of  
397 the time since diagnosis for the previous waves, it restricted the analysis to those that  
398 were present in the last wave. Finally, we used a WHO recommended HbA1c cut-off to  
399 diagnose diabetes, due to the lack of a Mexico specific cut-off. There is some evidence that  
400 HbA1c may be affected by ethnicity (Sacks 2011). Hence, if Mexican ethnicity would lead  
401 to different HbA1c levels, the use of our cut-off could have led to misclassification based  
402 on the used biomarkers.

403 Despite these limitations, our findings bear important implications. First, the impact  
404 of self-reported diabetes on labor outcomes in Mexico seemed mostly limited to its effect  
405 on employment probabilities. Second, its effect on employment was much stronger for  
406 females, though the underlying reasons for this remain unclear. Potential explanations  
407 are that lower working hours or wages for women make a dropout less costly. Other  
408 evidence suggests that women with diabetes are in worse metabolic health compared to  
409 men when they cross the diabetes threshold (Peters et al. 2015), making it more likely for  
410 them to drop out. Third, caution is needed when estimates based on self-reported diabetes  
411 are interpreted in terms of the entire population, i.e. extending to those with undiagnosed  
412 diabetes. Ideally, studies would include a biomarker analysis, acknowledge the differences  
413 between diagnosed and undiagnosed sub-populations, and carry out a separate analysis  
414 whenever feasible. If this is not possible, study conclusions about the effects of self-reported  
415 diabetes should be limited to this specific part of the population. This is of particular  
416 importance in LMICs where the share of undiagnosed diabetes is often high.

417 The large proportion of previously undiagnosed cases found in this paper indicates that

418 diagnosis—at least in Mexico—happens late or not at all. This may reduce the possibilities  
419 to prevent complications via treatment and self-management, increasing the risk of severe  
420 complications appearing premature. Earlier diagnosis and ensuing effective treatment may  
421 lighten the health and economic burden. Therefore, more research is needed to investigate  
422 the economic impact of diabetes over time. Longitudinal biomarker information could be  
423 used to observe the true duration and severity of diabetes as well as the time that passes  
424 till a medical diagnosis. This would allow for a better understanding of when adverse  
425 economic effects start to appear. Further, future research should investigate how time of  
426 diagnosis and treatment of diabetes affect the occurrence of adverse labour market effects  
427 of diabetes. The results of such research could allow costing studies to include more  
428 detailed information on the indirect costs of diabetes; or inform cost-effectiveness analyses  
429 that aim to include a measure of the potential benefit of the intervention to employers or  
430 society at large.
